

An ultra fast and sensitive detection of 165 drugs of abuse in human urine using polarity switching ultra performance liquid chromatography tandem mass spectrometry

Sachin Dubey, Shobha Ahi, Alka Beotra*, Tejinder Kaur, Shila Jain National Dope Testing Laboratory, Ministry of Youth Affairs and Sports, CGO Complex, Lodhi Road, New Delhi, 110003, (INDIA) E-mail : drabeotra@gmail.com

ABSTRACT

The screening of wide variety of prohibited substances in a time bound manner by adhering to latest World Anti-Doping Agency (WADA) guidelines is a challenging task for doping control laboratories. The revised criterion of detection limits (WADATD2013MRPL) has further required the doping laboratories to review their testing procedures. The present work was aimed at developing a fast, sensitive and robust analytical method based on solid phase cleanup (SPE) and ultra-performance liquid chromatography tandem mass spectrometry (UPLC-MS/MS) to achieve the required detection levels. The method development involved optimization of deconjugation of phase II metabolites, SPE using mixed-mode ion cartridges for extraction of analytes of wider chemistries; and fast polarity switching UPLC-MS/MS detection. The developed method was validated to detect approximately 165 compounds and/or metabolites prohibited by WADA. The eight minutes runtime allowed testing of approximately 180 samples in 24 hours at the limit of detection (LOD) of 50% below required detection levels. © 2015 Trade Science Inc. - INDIA

INTRODUCTION

The detection and identification of prohibited compounds and methods of doping has been regulated for sports drug testing laboratories by World Anti-Doping Agency (WADA). The WADA publishes a prohibited list every year consisting of wide range of pharmacological classes of drugs^[1]. WADA creates respective technical documents that outline minimum required performance limits (MRPL) as well as international standard for laboratories (ISL), which accredited doping control laboratoriesmust

ACAIJ, 15(8) 2015 [319-338]

follow^[2]. The prohibited list covers nine pharmaceutical classes of substances (e.g., anabolic steroids, corticosteroids, stimulants, diuretics, anti-estrogens etc), three forbidden doping methods (e.g., substance for enhancement of oxygen transfer, chemical and physical manipulation and gene doping), and two groups of analytes alcohol and â-blockers are prohibited in specific activities^[1]. Therefore, numerous technical approaches are needed to analyse the great diversity of doping agents.

Anti-doping analysis is conducted in two steps. Initially, screening of samples is performed, in the

case of a suspiciousresult; an additional selective confirmation is carried out^[3]. As every sample has to be screened, the screening method has to be highly sensitive and specific to ensure identification of suspected sample and in the same time should minimize the probability of false suspects. Doping analysis requires the use of several different chromatographic, mass spectrometric and immunological methods^[4-7] which makes it mandatory for all the doping control laboratories to have a number of separate analytical procedures, thereby making screening of each sample more complex, time-consuming and laborious. Therefore, it has become necessary to develop high-throughput techniques to screen in a single method a large set of compounds with different physicochemical properties avoiding false negatives and false positive results.

In the last decade, the suitability of liquid chromatography-tandem mass spectrometry (LC-MS/MS) has been demonstrated as a technique of choice over traditional gas chromatography mass spectrometry (GC-MS) methods for multi-target screening due to the development of electrospray ionization (ESI) sources which operates at atmospheric pressure^[8-11]. This capability allows the detection of both lowand high-molecular weight compounds^[12].

The ultra performance liquid chromatography (UPLC) based methods for screening analyses have emerged in the anti-doping field. The advantages of UPLC (in which columns are packed with sub-2µ particles operating at pressures up to 1000 bar) have been demonstrated to rapidly and efficiently separate drugs and related substances^[13,14]. Due to the reduced analysis time, peaks become very narrow and an adapted detection device is thus mandatory. Mass spectrometers with fast scanning like triplequadrupole (QQQ) are often coupled to UPLC and used in tandem mode by monitoring ion transitions^[15,16]. Modern QQQ instruments offer very fast acquisition cycle times and polarity switching usually expanding the number of analytes which can be detected in a single run. Numerous methods have been employed in the past decade conjoining UPLC with QQQ mass spectrometer (UPLC-MS/MS)for identification of variety of doping agents^[15-17].

The choice of development of a suitable sample

Analytical CHEMISTRY An Indian Journal pre-treatment for a screening purpose is a challenge as the method should provide good extraction yields for a combination of analytes with very different physico-chemical properties (neutral, basic and acidic, lipophilic and hydrophilic). Moreover, human urine is usually a very dirty matrix so it requires an extraction technique in which the impurities of the sample should be eliminated to avoid any possible unwanted interference of the matrix. The diversified categories of drugs of abuse mostly contain basic compounds with exceptions of neutrals (glucocorticosteroids) and acidics (diuretics). Besides, the huge number of different endogenous components normally found in urine makes the selective detection of analytes at low concentration very challenging. Recently, various methods have been developed to detect the banned compounds in human urine using dilute and shoot approach^[18-19]. The dilute and inject approach is certainly fast, but it does not allow for the detection of analytes at very low concentrations and does not include deconjugation of glucuronides^[20-21]. Hydrolysis is mandatory to remove the glucuronide moieties attached to several doping agents during phase II metabolism. Liquid liquid extraction (LLE) may be used for the sample purification but it faces some pitfalls. To cover a wide range of different drugs, two consecutive extractions, one at basic and the other at acidic pH, is required. In addition, LLE requires careful separation of the phases and can be time consuming and tend to use large volumes of solvent. Moreover, the sample extracts are not very clean.

The most preferred technique for said requirement is solid-phase extraction (SPE) as it requires less washing and cleaning steps and blocks the impurities of the sample within the cartridge. A single or multiple-stage SPE has been applied for the sample preparation methods in various fields of doping^[20-22]. In particular, a single mixed-mode cartridge is reliable for the fractionation of acid, neutral and basic drugs from biological samples because the drugs are adsorbed separately by hydrophobic or ion-exchange interaction on to the cartridge.

To ensure consistency of the measurements amongst doping control laboratories, WADA defines the MRPL, which is the concentration of a prohib-

ited substance at which the laboratories are expected to detect the prohibited drug/s. From January 2013, WADA has revised the MRPL criterion for the detection of drugs by the anti-doping laboratories wherein, the MRPL of various drugs has been reduced from 20-80% (TABLE 1)^[23]. In addition, the criteria for limit of detection (LOD) is also revised (TDMRPL2013) which states that the laboratory's method validation of the initial testing procedure shall include the estimation of the LOD for each compound and the estimated LOD shall not be higher than 50% of the MRPL. The revised MRPL and LOD criterion applicable from January 2013 has further necessitated the need to review and revise testing procedures in the doping laboratories to achieve the targeted MRPLs.

The lower detection limits enforced in the new technical guidelines of WADA has required improving the existing screening method by LC-MS/MS in our lab in order to 1) develop a comprehensive and fast analytical method based on multi target approach reducing the burden of number of detection methods and analysis time 2) method sensitive enough to achieve the detection levels. Hence, the aim of this work was to develop a high throughput and sensitive screening method for the detection of various drugs at or below the WADA TD2013 MRPL. It was required to derive the extraction procedure to extract analytes with a very wide range of chemistries as well as the detection method so as to improve the LOD of drugs.

Hence, a three step strategy was made for the overall improvement of the method: i) Enzymatic hydrolysis for the deconjugation of phase II metabolites (glucuronides), ii) SPE using mixed mode cartridges for the execration of acidic, basic and neutral molecules in single step and, iii) identification of drugs on highly sensitive and upgraded instrument i.e. UPLC-MS/MS using fast polarity switching. The developed method would allow fast and

sensitive detection of various categories of drugs well within the requirement of WADA TD2013 MRPL guidelines with scope for inclusion of newer entities due to use of dedicated though comprehensive sample clean up and detection technique.

MATERIALS & METHODS

Chemicals and reagents

All reagents were of analytical grade or HPLC grade: acetonitrile, and ethyl acetate were purchased from Qualigens Mumbai, India. Tertiarybutyl methyl ether, and formic acid 98% were supplied by Merck, Mumbai, India. Out of the 165 compounds screened in the method, the certified reference materials of 152 drugs were available in the laboratory. The certified reference compounds were purchased mainly from National Measurement Institute (NMI, Sydney, Australia), Cerilliant (Round Rock, Texas) and Sigma-Aldrich (St. Louis, MO), or from the pharmaceutical manufacturer; several were kindly donated by other anti-doping laboratories. In some cases, where reference material was not available, urine samples obtained from drug administration studies were used. The mobile phases for UPLC were filtered through a 0.2 µm PTFE filter. Ultra high purity nitrogen was obtained from nitrogen generator plant installed at the laboratory. Water was purified using a Milli-Q water purification system installed in the laboratory (Millipore, Bedford, USA).

Solutions

Stock standard solutions of the 152 substances were prepared separately at a concentration of 1 mg/ ml in suitable solvent depending on the solubility and stored at -20 °C in glass vials fitted with PTFE caps. The standard mixtures were prepared and were spiked afresh in quality controls (QCs) every time. Allsolutions are evaluated periodically for degradation by comparing peak areas, peak area ratios and peak shapes to historical values.

System suitability standards

The internal standards (ISTDs) were used as the system suitability standards (SSS) containing six se-

Analytical CHEMISTRY An Indian Journal lected analytes of different molecular weights, polarities and chemical classess viz. 17- α methyltestosterone (AAS), mefruside (diuretic), formoterol d-6 (β 2 agonist), *dl*-amphetamine d6 (stimulant), bupranolol (beta-blocker) and diphenylamine (stimulant). These ISTDs were added to each sample and were monitored in terms of peak area and retention time. All ISTDs were monitored in positive ionization except mefruside which was monitored in negative ionization.

Quality control samples

Drug-free urine samples were collected from 20 different volunteers divided into 2 ml aliquots and kept frozen at <10 °C in polypropylene tubes prior to use. The Quality Control (QC) samples which were run in each assay were prepared by spiking the blank urine samples (2 ml) with theworking standard mixture solutions to achieve the necessary concentration at MRPL of each category of prohibited class. Negative quality control (NQC) samples were spiked with only with the ISTDs. The ISTDs were added at the following concentration; 17- α methyltestosterone (50 ng/ml), mefruside (50 ng/ml), formoterol d-6 (30 ng/ml), dl amphetamine d6 (50 ng/ml), bupranolol (50 ng/ml) and diphenylamine (50 ng/ml).

Sample preparation

To two ml of urine sample aliquots internal standards at defined concentration were added. The urine samples were hydrolysed by β –glucuronidase (*E.coli*) enzyme at 60°C for an hour after optimizing pH 7.0 using 0.2 M phosphate buffer. Hydrolyzed samples were loaded on to the Oasis HLB cartridges pre-equilibrated with 2 ml methanol and 2 ml water. After application of the samples, the cartridges were washed with water. Elution of analytes was performed with 3 ml methanol. Samples were evaporated under a gentle nitrogen flow at 60 °C and then were reconstituted into 100 il of a solution of mobile phase (acetonitrile : 1 % formic acid ; 50:50 ; v/v) and transferred into conical autosampler vials for analysis.

Instrumentation

The liquid chromatographic system was Waters® Aquity UPLC equipped with degasser, binary pump,

autosampler thermostated at 5°C and column compartment. The column employed was Acquity BEH C18, 2.1mm X 100mm X 1.7 μ particle size from Waters (Millford, USA). Samples were stored at 4 °C in the autosampler prior to analysis.

The LC effluent was pumped to an Atmospheric Pressure Ionization (API) 5500 QQQ mass spectrometer (AB Sciex, Darmstadt, Germany). The ion source was operated under fast polarity switching (50 ms) electro spray ionization mode. The analytes and the ISTDs were detected utilizing multiple reaction monitoring (MRM) of diagnostic precursor-product ion transitions at dwell times of 5 ms. The instrumental conditions are depicted in TABLE 2. For optimization of the declustering potential and the collision energy solutions of pure reference compounds of each analyte were directly injected using a 1 ml syringe at flow rate of 10 ml/min. Nitrogen was used as collision gas delivered from a nitrogen generator (Anest Iwata Motherson, Japan). Target MRMs and compound dependant parameters for each analyte are listed in TABLE 3. Data acquisition, data handling, instrument control and data processing were performed using Analyst 1.5.2® Software (AB Sciex).

Method development and validation

The analytical method was developed and validated as per the WADA guidelines for the anti-doping laboratories^[26]. For validation the parameters recovery percentage, specificity, ion suppression, intra and inter-day precision, LODand robustness were determined.

Recovery

The recoveries of all target compounds tested in urine were determined at the MRPL as regulated by WADA. Ten drug-free urine samples were fortified at the MRPL concentration with all of the compounds tested, another ten drug-free urine specimens were extracted according to the described SPE protocol, and all compounds tested were added to the elution solvent before evaporation. The direct standards (without extraction) corresponded to 100% recovery. Recovery was evaluated by comparing the mean peak-area ratio of the analyte and the ISTD in spiked and direct samples.

Specificity

Evaluation of specificity was carried out by analyzing six spiked (at MRPL) and six different blank urine samples collected from six different healthy volunteers to test for interfering signals in the selected MRM chromatograms at expected retention times of the analytes. The specificity was also demonstrated by studying 100 urine samples from antidoping controls that had previously tested negative with reference methods to demonstrate that no interferences were detected at the retention time of the analytes under investigation. Amongst these few samples containing common over-the-counter medicaments, such as paracetamol, ibuprofen or salicylates were also analysed. The specific gravity of these samples ranged between 1.001-1.030.

Ion suppression/ion enhancement

The extent of ion suppression or enhancement was investigated by analysing six different blank urine samples via post-column continuous infusion of a mixture of the reference compounds (10 μ g/mL at a flow rate of 7 μ L/min)^[24].

previously declared positive for one of the substances included in this screening using earlier method. In addition, hundred urine samples which were already reported negative by previous method were also reanalyzed.

Precision

Intra-day precision was determined at MRPL for each compound using five replicates of spiked urine samples. The corresponding inter-assay precision was calculated from samples prepared and analyzed on three different days (n=5/day). The precision of the method was determined by calculation of the coefficient of variation (CV%) of the area ratio of the ion transition of the analytes and the internal standard.

Limit of detection

The LOD was defined as the lowest concentration of analyte (S/N>3) that can be identified, measured and reported. The LOD was estimated via signal to noise ratio (S/N) of the lowest abundant MRM transition using ten blank samples and ten fortified samples at concentration levels from 2-50 % of MRPL for different compounds.

Applicability to routine doping control samples

Analytical CHEMISTRY An Indian Journal

The method was applied to fifty urine samples

RESULTS AND DISCUSSION

A sensitive and high-throughput screening method for the determination of 165 prohibited substances from 10 different classes viz: S1. anabolic agents including clebuterol (21), S2. β -2 agonists (03), S4. hormones and metabolic modulators (14), S5. diuretics and masking agents (30), S6. stimulants (51), S7. narcotics (04), S8. cannabinoids (01), S9.glucocorticosteroids (21), P2. beta blockers (19) and M1. Method for oxygen enhancement (01) was developed and validated for qualitative analysis.

To achieve the MRPL levels as per WADA TD2013MRPL it became necessary to have a more sensitive method. The use of UPLC-MS/MS system to achieve the high sensitivity level proved to be beneficial but at the same time it required a specific enough sample preparation method with cleaner extracts.

Sample preparation

A generic sample preparation method was developed which was able to isolate and preconcentrate analytes of different classes i.e. corti-

Paloet

costeroids, anabolic steroids, β 2 agonists, diuretics, stimulants, narcotics, betablockers and hormone and metabolic modulators in one procedure from urine samples. The classical sample preparation method previously employed in the laboratory consisted of hydrolysis by β -glucuronidase (*E. coli*) followed by two step liquid-liquid extraction: extraction in TBME at pH 9-10 and extraction in ethyl acetate at pH 4^[25,26]. While this method gave optimum results and was in-use in laboratory for 5 years, but few impediments were observed after the applicability of WADA TD2013MRPL which gave rise to the need of shifting sample preparation method to solid phase extraction procedure.

The approach towards sample extraction in this study was aiming to recover wide range of chemistries of the acidic, basic and neutral in one single sample. The protocol used for the SPE in this study was based on mixed mode cartridges optimized to provide best extraction recoveries. Several mixed mode cartridges were tested. Higher extraction yields were obtained with Oasis HLB cartridges as compared with other cartridges. The pH dependence of the recoveries of acidic, basic and neutral drugs was examined to set the condition of charging the sample into the column. It was found that an effective recovery of all the compounds could be achieved while keeping the sample pH neutral prior to loading the sample on cartridge. The greatest impediment of SPE of urine samples is the high rate of column blockage experienced during sample extraction. Sample blockage could result in the loss of significant throughput. Centrifugation of urine sample prior to sample preparation has been used to overcome this problem.

In addition, the method uses only 2 ml of urine volume for the analysis of 165 drugs from 10 different categories. In general the volumeis 2–4 times lower than the volume normally used for screening of such high number of drugs in routine doping control procedures. This is useful since in doping control a limited amount of urine is available for screening and confirmation of a wide range of substances. The effectiveness of the de-conjugation step was evaluated in every sample by monitoring the signal of D3-codeine glucuronide and D3-6 β morphine glucu-

ronide, together with their deconjugation products D3codeine and D3-6 β morphine. ISTDs were selected to correct random or systematic errors in the positive and negative ESI modes. Stable isotopically labeled standards are generally preferred for biological matrices (especially inquantitative assays), as they are structurally similar to the analyteand eluted at similar retention time. However, since this study was based on qualitative analysis the use of isotopically labeled internal standards was not a mandate. Hence, the choice of internal standards from various categories viz. 17- α methyltestosterone (AAS), mefruside (diuretic), formoterol d-6 (β 2 agonist), dl amphetamine d6 (stimulant), bupranolol (beta-blocker) and diphenylamine (stimulant) aided in keeping a quality check on system suitability.

Chromatographic conditions

UPLC improves chromatographic resolution, speed and sensitivity, and when coupled to fast scanning mass spectrometry, facilitates rapid, high-throughput analysis. Therefore, a UPLC system with Acquity BEH C18, 2.1mm X 100mm X 1.7 μ column was used. The chromatographic optimizations allowed to separate and detect a mixture of 165 doping substances within 8 min. Majority of compounds were basic (68%) (e.g., stimulants, β -blockers) followed by acidic substances (22%) (e.g., diuretics, stimulants) with the remainder being neutral analytes (e.g., few diuretics, anti-estrogens).

The chromatographic conditions were chosen in an appropriate way and were found to be compatible with the API source. The choice for the mobile phase was adopted from the previous screening method employed in the laboratory^[25-26]. A gradient starting at 95% aqueous buffer (1% Formic acid, pH 3.5) was required to ensure sufficient retention for hydrophilic compounds. To avoid column blockage a pre-column has been used. Over 1500 analyses were conducted with the same analytical column without any loss in chromatographic performance. In the beginning of the gradient, mostly amphoteric compounds with low logD values (log P at defined pH) eluted, reflecting their hydrophilicity. Peak shapes were generally good although some splitting of peaks was observed in the beginning of the gradient. Compounds with the same retention time were readily identified by their mass spectrum.

329

Analytical CHEMISTRY An Indian Journal

Figure 1 : Multiple reaction monitoring (MRM) ion chromatogram peaks of various analytes showing identification capability of the method

Mass spectrometry

For mass spectrometric method development individual standard solutions of all drugs were optimized in both positive and negative ESI modes. As expected, higher signal intensity was obtained in positive ESI mode for basic and neutral compounds and, negative ionization mode was preferred for acidic molecules. The method was optimized to detect the drugs, using the MRM pair comprising of precursor and product ions. The product ions (Q3) were obtained during the collision of the precursor ions (Q1) in collision cell (Q0). The corresponding retention times, MS and MS/MS spectra were then used to obtain structural information. All the compounds showed good sensitivity and were separated in 8 minutes of runtime. Analyte identification in the screening step was based both on retention time (tR) and m/z of a diagnostic ion (MRM).

The capability of inclusion of fast polarity switching (50 ms) in the method ensured an optimized ionization, of acidic or basic analytes in the same analytical run. While 142 analytes were detected in positive ionization mode mainly as protonated molecule $[M+H]^+$, 23 analytes were detected in negative ionization mode as deprotonated molecule $[M-H]^-$.

Method validation

The screening method developed in the study aimed at qualitative analysis. The identification was based on the compound's chromatographic and mass spectrometric properties. For every batch of urine samples, cleaning of curtain plate with methanol was performed before sample analysis. A QC sample was injected at the beginning and end of the analytical sequence to verify that the analytical process was in control. No significant change in sensitivity was observed between the two QC sample injections throughout this study, indicating that the method is robust for routine use. No remarkable variation in results of inter day, intraday & inter personal studies was observed, confirming that the method is sufficiently reliable and reproducible.

Specificity

The evaluation of specificity in six different spiked and six different blank urine samples showed no interfering signals in the selected MRM chromatograms at expected retention times of the analytes. Moreover, the analysis of hundred independent negative urine samples allowed extensive evaluation of the specificity of the method. Co-elutions with endogenous substances were observed for prednisolone, boldenone, methyldeinolone, formebolone, amphetamine, oxiloferine and methylphenidate. Therefore, more specific fragments were obtained for these analytes and were incorporated in the method.

Identification capacity

All the 165 compounds showed good identification capacity yielding good peak shapes with maximum possible number of dwell times. The effect of dwell time on sensitivity has been reported by Herrin et al.^[27]. The longer dwell times led tobetter sensitivity, although the gain in sensitivity was moderate beyond 20ms. The pitfall of longer dwell times resulted in a longer duty cycle time that had a negative impact onchromatographic data points, particularly for the narrow peaks. All 165target compounds could be easily detected with sufficient sensitivity at the dwell time of 5 ms which was used in subsequent MRM experiments (Figure 1).

Ion suppression/ion enhancement

Ion-suppression/ion enhancement, sometimes re-

ferred to as matrix effect, is acommon problem in API mass spectrometry^[28,29]. No significant ion suppression or enhancement was observed on six different blank urines which were analyzed with continuous co-infusion of the target analytes (10 μ g/mL at a flow rate of 7 μ L/min) via T connector.

Carryover

Carry-over, which is the appearance of an analyte signal in ablank (drug-free extracted matrix) injection subsequent to analysis of high concentration samples, is a common problem in LC-MS/MS methods^[30,31]. This problem occurs due toretention of analytes by adsorption on active surfaces of the auto injector system, solvent lines, SPE, or the analytical column. The carryover is also dependenton the type of analyte and the dynamic range of an assay. Hence, the issue becomes exacerbated after the injection of an analyte at high concentrations. The carry-over effect was evaluated by injecting the analytes spiked in urine at 1 µg/ml, followed by injection of three blank samples. The carry over effect of less than 0.5% in the first blank sample was demonstrated by the following analytes viz.benfluorex, fencamfamine, fenethylline and timolol, but no analyte was found in the subsequent blankurine samples. Therefore, it was concluded that if any of the targeted analyteis found to be positive in two subsequent samples (if $\leq 1\%$ of peak area than in the preceding sample), they should be re-injected with two urine blanks in between.

Precision

For intra-day precision the relative peak area responses for samples spiked at the MRPL level and ana-

Figure 2 : Limit of detection (LOD) % as compared to WADA MRPL of various categories of banned drugs.

*Interday & intraday precision estimated at the target concentration of each analyte.

lyzed via the screening method showed CV% values ranging from 1.2% (timolol) to 10% (pholedrine). While for inter-day precision the CV% ranged from 2.4% (sotalol) to 11.3% (benfluorex) (TABLE 4). The results indicate that the method has acceptable limits of repeatability and reproducibility for day-to-day screening analysis. This is an important aspect while proceeding for confirmation of the suspicious sample.

Recovery

The recovery for all compounds studied ranged from 25% (octopamine) to124% (boldenone). A wide variation in extraction recoveries is to be expected considering that the analytes under study are a combination of various chemistries like aliphatic, aryl, phenolic. alka-

loids, phenanthreine, piprazine, thiazide, with varying functional groups like OH, NH_2 , CO, COOH etc. It is notably important that the compounds showing lower recovery (25-60%) could also be detected at equal to or less than 50 % of MRPL level (TABLE 4).

Limit of detection (LOD)

The LOD estimated in ten fortified samples at concentration levels from 2-100 % of MRPL for different compounds was found satisfactory. It was possible to achieve the LOD ranging between 10-50% of MRPL values of different analyes (Figure 2). For compounds in which recovery was found to be below 50%, the LOD was found much below the MRPL yielding a good detection capability (TABLE 3). The developed method

satisfied WADA's criteria in terms of sensitivity for all the 165 compounds studied.

Relative retention time

In order to use *t*R as a parameter for LC behavior, it was important o demonstrate its reliability. The relative retention times (RRTs) were observed in three consecutive batches and the precision was determined by calculation of the coefficient of variation (CV %). During this period, the preparation of fresh mobile phases and maintenance of the ESI source was performed daily. It was found that the CV % did not exceed 1% for any of the compound (TABLE 4). Therefore, *t*R was accepted as a relevant and reliable identification criterion for the analytes. The I.S.S were monitored in each sample to detect variance in LC performance, sensitivity or *t*R variations.

Applicability to routine doping control samples

The suitability of the developed method for target analysis was proven by analyzing 50 urine samples previously declared positive for substances included in the screening method. No false negative samples were found. However, these samples showed good sensitivity and identification capability towards the analyte of interest (Figure 1). Furthermore, the testing of 100 urine samples screened as negative earlier, using previous method were screened as negative using the present method. The inclusion of two MRM transitions in the screening method further ensured to improve the specificity.

The MS source cleaning was performed every 100 urine samples. The pre-column was changed after 1500 injections, and the column was replaced after 3000 injections based on daily SSS monitoring. The current method takes only 8 min. of runtime to analyze 1 sample against the 16 min runtime of the traditional method. This has significantly improved the throughput where 90 samples could be detected in 12 hours against 45 samples per 12 hours using the old method. This method was thus considered beneficial in terms of analysis time, cost effectiveness, resources and requisite guidelines.

In comparison to the earlier screening procedure a real gain in time was obtained since the sample treatment was very fast, and the screening of the 165 analytes was performed using a single generic

Analytical CHEMISTRY An Indian Journal method. It has been in routine use for more than 6months involving the analysis of over 1500 urine samples. Only one UPLC columns was needed for this period. Use of the old screening procedure has been discontinued after running both methods in parallel for 1 month.

CONCLUSION

The experiments presented in this work were based on UPLC-MS/MS. A fast, generic and sensitive method was developed for the analysis of 165 compounds achieving LOD between10 to 50% of WADA MRPL. The method was validated according to the International Standard for Laboratories (ISL) described in the World Anti-Doping Code and was selective enough to comply with the World Anti-Doping Agency recommendations. The developed method could be of significant use in bioanalytical, forensic & pharmaceutical & clinical analysis.
